A New Way To Speed Up Recursion in Relational Databases

Yangjun Chen*

ABSTRACT
Composite object represented as a directed graph is an important data structure which requires efficient sup-port in CAD/CAM, CASE, office systems, software man-agement, web databases and document databases. It is cumbersome to handle such an object in relational database systems when it involves recursion relationships. In this paper, we present a new encoding method to support the effi-cient computation of recursion. In addition, we devise a linear time algorithm to identify the sequence of spanning trees (forests) w.r.t. a directed acyclic graph (DAG), which covers all the edges of the graph. Together with the new en-coding method, this algorithm enable us to compute recur-sion w.r.t. a DAG in time \(O(e)\), where \(e\) represent the number of the edges of the DAG. More importantly, this method is especially suitable for a relational environment.

INTRODUCTION
It is a general opinion that relational database systems are inadequate for manipulating composite objects which arise in novel applications such as web and document databases [MMM97, ACCM97, CA98, CA99], CAD/CAM, CASE, office systems and software man-agement [BKKG88, Te96]. Especially, when recursive relationships are involved, it is cumbersome to handle them in relational systems.

A composite object can be generally represented as a directed graph. For example, in a CAD database, a composite object corre-sponds to a complex design, which is composed of several subdesigns [BKKG88]. Often, subdesigns are shared by more than one higher-level designs, and a set of design hierarchies thus forms a directed acyclic graph (DAG). As another example, the citation index of scient-ific literature, recording reference relationships between authors, constructs a directed cyclic graph. As a third example, we consider the traditional organization of a company, with variable number of manager-subordinate levels, which can be represented as a tree hierarchy. In a relational system, composite objects must be fragmented across many relations requiring joins to gather all the parts. A typical approach to improving join efficiency is to equip relations with hidden pointers fields for coupling the tuples to be joined [Ca90].

Recently, a new method has been proposed by Teu-hola [Te96], in which the information of the ancestor path of each node is packed into a fix-length code, called the signa-ture. Then, the operation to find a transitive closure can be performed by identifying a series of signature intervals. No joins are needed. Using Teu-hola’s method, CPU time can be improved up to 93% for trees and 45% for DAGs in compar-ison with a method which performs a SELECT command against each node, where the relation to store edges is equipped with a clustering index on the parent nodes [Te96].

In this paper, we follow the method proposed in [Te96], but using a different encoding approach to pack “ancestor paths”. For example, in a tree hierarchy, we associate each node \(v\) with a pair of integers \((a, b)\) such that if \(v\)’, another node associated with \((a’, b’)\), is a descendant of \(v\), some arithmetic-ical relationship between \(a\) and \(a’\), as well as \(b\) and \(b’\) can be determined. Then, such relationships can be used to find all descendants of a node and the recursive closure w.r.t. a tree can be computed very efficiently. This method can be generalized to a DAG or a directed graph containing cycles by decomposing a graph into a sequence of trees (forests), in which the approach described above can be employed. As we can see later, a new method can be developed based on the techniques mentioned above in which recursion can be evalu-atated in \(O(e)\) time, just as an algorithm using adjacency lists. (The adjacency list is a common data structure to store a graph in computa-tional graph theory [Mc94].) However, our method is especially suitable for the implementation in a relational environment.

TASK DEFINITION

We consider composite objects represented by a directed graph, where nodes stand for objects and edges for parent-child relationships, stored in a binary relation. In many applications, the transitive closure of a graph needs to be computed, which is defined to be all ancestor-descendant pairs. A lot of researches have been directed to this issue. Among them, the semi-naive [BR86] and the logarithmic [VB86] are typi-cal algorithmic solutions.

Another main approach is the ma-terialization of the closure, either partially or completely [AJ90, J90]. Recently, the implementation of the transitive closure algorithms in a relational environment has received extensive attention, including performance and the adaptation of the traditional algorithms [ADJ90, AJ90, IRW93, DR94].

The method proposed in this paper can be characterized as a partial materialization method. Given a node, we want to compute all its descendants efficiently based on a special-ized data structure. The following is a typical structure to ac-commodate part-subpart relationship [CS92]:

- Part(Part-id, Part-rest)
- Connection(Parent-id, Child-id, Conn-rest)

where Parent-id and Child-id are both foreign keys, referring to Part-id. In order to speed up the recursion evaluation, we’ll associate each node with a pair of integers which helps to recognize the ancestor-descendant relationship.

In the rest of the paper, the following three types of graphs will be discussed:

1. Tree hierarchy, in which the parent-child relationship is of one-to-many type, i.e., each node has at most one parent.
2. Directed acyclic graph (DAG), which occurs when the relationship is of many-to-many type, with the re-striction that a part cannot be sub/superpart of itself (directly or indirectly).
3. Directed cyclic graph, which contains cycles.

Later we’ll use the term graph to refer to the directed graph, since we do not discuss non-directed ones at all.

LABELING A TREE STRUCTURE

In the method proposed in [Te96], each node \(v\) is associated with an interval \((l, h)\), where \(l\) and \(h\) are two signatures each consisting of a bit string. These bit strings are constructed in such a way that if the interval associated with a descendant of \(v\) is \((l’, h’)\), then \(l E l’\) and \(h > h’\) hold. Although this meth-od is incomparably superior to a trivial method, it suffers from the following disadvantages:

1. This method is space-consuming since signatures tend to be very long.
2. The size of signatures has to be pre-determined. Different applications may require different signature lengths. This can be tuned only manually.

(3) There may exist the so-called signature conflicts, i.e., two nodes may be assigned the same signature.

In the following, we search for remedies for these three draw-backs. First, we discuss a tree labeling method to demonstrate the main idea of the improvement in this section. The discussion on general cases will be postponed to Section 4.

Consider a tree $T$. By traversing $T$ in preorder, each node $v$ will obtain a number $\text{pre}(v)$ to record the order in which the nodes of the tree are visited. In the same way, by traversing $T$ in postorder, each node will get another number $\text{post}(v)$. These two numbers can be used to characterize the ancestor-descendant relationship as follows.

**Proposition 1.** Let $v$ and $v'$ be two nodes of a tree $T$. Then, $v'$ is a descendant of $v$ iff $\text{pre}(v') > \text{pre}(v)$ and $\text{post}(v') < \text{post}(v)$.

**Proof.** See [Kn73].

If $v'$ is a descendant of $v$, then we know that $\text{pre}(v') > \text{pre}(v)$ according to the preorder search. Now we assume that $\text{post}(v') > \text{post}(v)$. Then, according to the postorder search, either $v'$ is in some subtree on the right side of $v$, or $v'$ is in the subtree rooted at $v$; which contradicts the fact that $v'$ is a descendant of $v$. Therefore, $\text{post}(v')$ must be less than $\text{post}(v)$.

The following example helps for illustration.

**Example 1.** See the pairs associated with the nodes of the graph shown in Fig. 1(a). The first element of each pair is the preorder number of the corresponding node and the second is the postorder number of it. Using such labels, the ancestor-descendant relationship can be easily checked.

![Labeling a tree](image)

For example, by checking the label associated with $b$ against the label for $f$, we know that $b$ is an ancestor of $f$ in terms of Theorem 1. We can also see that since the pairs associated with $g$ and $c$ do not satisfy the condition given in Theorem 1, $g$ must not be an ancestor of $c$ and vice versa.

According to this labeling strategy, the relational schema to handle recursion can consists of only one relation of the following form:

```
(Node(Node_id, label_pair, Node_rest),
```

where `label_pair` is used to accommodate the preorder number of each node, denoted `label_pair preorder` and `label_pair postorder`, respectively. Then, to retrieve the descendants of node $x$, we issue two queries. The first query is very simple as shown below:

```
SELECT label_pair
FROM Node
WHERE Node_id = x
```

Let the label pair obtained by evaluating the above query be $y$.

Then, the second query will be of the following form:

```
SELECT * FROM Node
WHERE label_pair.preorder > y.preorder AND label_pair.postorder < y.postorder
```

From the above discussion, we can see that the three draw-backs of Teuhola’s method [Te96] mentioned above can be eliminated: (1) each node is associated with only a pair of integers and therefore the space overhead is low; (2) the size of each label pair remains the same for all applications; (3) there is no signature conflicts since each label pair is different from the others.

In the following, we show another two important techniques to identify the sibling relationship and the parent-child relationship.

For the first task, consider a new labeling method as shown in Fig. 1(b). First we assign 1 to the root; then, during the breadth-first traversal we number the children of each node consecutively from $x + 2$, where $x$ is the largest number assigned so far. We call such a labeling method the sibling-code. Then we can associate each parent node with an interval $[a, b]$ such that each child’s sibling-code $s \in [a, b]$. Therefore, two nodes are siblings iff their sibling-codes be-long to the same interval.

To identify the parent-child relation, we associate each node with a level number. The root has the level number 0. All the children of the root have the level number 1, and so on. Then, if node $x$ is the ancestor of $y$ and at the same time $l(x) = l(y) - 1$ ($l(x)$ stands for the level number of $x$), then we know that $x$ is the parent of $y$.

**GENERALIZATION**

Now we discuss how to treat the recursion w.r.t. a general structure: a DAG or a graph containing cycles. First, we ad-dress the problem with DAGs in 4.1. Then, the cyclic graphs will be discussed in 4.2.

Recursion w.r.t. DAGs

We want to apply the techniques discussed above to a DAG. To this end, we divide a DAG into a set of spanning trees (forests). This method shares the flavor of Teuhola’s [Te96].

But our decomposition strategy is quite different from [Te96]. In [Te96], a DAG is decomposed into a set of spanning trees which are separated from each other, i.e., there are no common nodes between any two spanning trees while in ours two spanning trees (forests) may have common nodes. The advantage of our method can be seen in the following discussion.

In the following, we concentrate on only single-root graphs for simplicity. But the proposed method can be easily extended to normal cases. We construct a sequence of spanning trees (forests) w.r.t. a DAG with the single-root $r$, which covers all the edges of $G$. First, we extract the spanning tree (forest) from $G$, which contains all nodes of $G$, denoted $T_{\text{max}}(G)$. Then, we remove $T_{\text{max}}(G)$ and subsequently all isolated nodes from $G$, getting another graph $G_{1}$. Next, we construct a spanning tree (forest) w.r.t. $G_{1}$, $T_{\text{max}}(G_{1})$. We repeat this process until the remaining graph becomes empty. It is therefore easy to see that all $T_{\text{max}}(G)$ can be obtained in $O(n + e)$ time by repeating graph search procedure $k$ times, where $n$ and $e$ represent the number of the nodes and the edge sets of the DAG, respectively. However, this time complexity can be reduced to $O(n + e)$ by implementing an algorithm which computes such a sequence in a single-scan.

For a DAG $G = (V, E)$, we represent the sequence of spanning trees (forests) $T_{\text{max}}(G)$ as follows:

$T_{\text{max}}(G) = (V_{1}, E_{1}), T_{\text{max}}(G) = (V_{2}, E_{2}), T_{\text{max}}(G) = (V_{3}, E_{3}), \ldots, T_{\text{max}}(G) = (V_{m}, E_{m})$,

where $V_{i}$ stands for the set of nodes in $G_{i}, V_{i} = (i = 2, \ldots, m+1)$ for the set of nodes in $G - E_{i} \cup E_{i} \cup \ldots \cup E_{m}$, and $m$ is the largest in-degree of the nodes of $G$.

In the following, we give a linear time algorithm to compute all $T_{\text{max}}(G)$'s.

The idea is to construct all $E_{i}, E_{2}, \ldots, E_{m}$ in a single scan. Dur-ing the graph search we compute, for each edge $e$ being scanned, the $i$ satisfying $e \in E_{i}$. Such $i$ can be defined to be the smallest such that if $e$ is put in $E_{i}$, the condition: each node in any $E_{j} (j = 1, \ldots, i)$ is visited only once, is not violated, where $E_{i}$ denotes the edge sets constructed so far. In the algorithm, we always chose an unvisited edge $e$ that is adjacent to edge $e^{' \in E_{i}}$ with the largest $i$. In the algorithm, we associate each
node $v$ with a label $l(v)$; $l(v) = 0$ indicates that $v$ has been reached by an edge of the forest $T_u(G_u) = (V, E)$. In the following algorithm, we assume that the nodes are numbered in terms of the depth-first search.

**Algorithm find-forest**

input: $G = (V, E)$
output: $E_1, E_2, \ldots, E_n$

begin
  $E := E := \ldots := E_n := \emptyset$;
  Mark all nodes $v \in V$ and all edges $e \in E$ “unvisited”;
  $l(v) := 0$ for all $v \in V$;
while there exist “unvisited” nodes do
  choose an “unvisited” node $v \in V$ with the largest $l$ and the smallest “depth-first” number $l$;
for each “unvisited” edge $e$ incident to $v$ do
  begin
    Let $u$ be the other end node of $e$ ($u \neq v$);
    $E_{\text{local}} := E_{\text{local}} \cup \{e\}$;
    $\Delta \leftarrow \{l(v) := l(u) + 1\}$;
    if $l(y) = l(v)$ then $l(y) := l(u) - 1$;
    Mark $v$ “visited”;
  end
Mark $x$ “visited”;
end

For example, by applying the above algorithm to the graph shown in Fig. 2(a), we will obtain the edges of three spanning trees shown in Fig. 2(b). In Appendix, we will trace the execution of the algorithm against Fig. 2(a) for a better understanding.

In the above algorithm, each edge is visited exactly once. Therefore, the time complexity of the algorithm is bounded by $O(n + e)$. For the following, we prove a theorem to establish the correctness of the algorithm.

**Figure 2: DAG and its node-disjoint maximum**

![Diagram](image)

**Proposition 2.** Applying Algorithm “find-forest” to a DAG $G$, a sequence of spanning forests (forests) w.r.t. $G$ will be found, which covers all of its edges.

**Proof.** First, we note that by the algorithm each edge will be visited exactly once and put in some $E_i$. Therefore, the union of all $E_i$’s contains all edges of $G$. To prove the theorem, we need now to specify that in every $E_i$ except the root nodes of $E_i$, each node can be reached along only one path, or say, visited exactly one time w.r.t. $E_i$.

Pay attention to the lines marked with **. If a node $u$ is visited several times along different edges, such edges will be put in different $E_i$’s. Therefore, in each $E_i$, we can be visited only once. By the line marked with ***, if an edge $(u, v)$ is put in some $E_i$, then an unvisited edge reaching $v$ afterwards will be put in $E_i$ or $E_i$. If in $E_i$, there is no edge reaching $v$ up to now (in this case, $l(v) < l(u)$ holds), the label of $v$ can be changed to $l - 1$. Then, if afterwards an unvisited edge reaches $v$, it will be put in $E_i$. In this way, in $E_i$, $v$ can be visited only once, which completes the theorem proof.

Now we can label each $E_i$ in the same way as discussed in the previous section. (A forest can be regarded as a tree with a virtual root which has a virtual edge linking each tree root of the forest.) In addition, we notice that a node may appear in several $E_i$. For example, in Fig. 2(b) node 6 appears in $E_1$ and $E_2$, while node 5 is occurs in all the three spanning trees. Then, after labelling each $E_i$, each node $v$ will get a pair sequence of the form: $(\text{pre}_i, \text{post}_i)$, $(\text{pre}_i, \text{post}_i)$, $(\text{pre}_i, \text{post}_i)$, where for each $i \in \{1, \ldots, m\}$, where for each $i \in \{1, \ldots, m\}$ ($m$ is the in-degree of $i$) stands for the preorder number and post-order number of $v$ w.r.t $E_i$.

In the subsequent discussion, we also say that a label belongs to some $E_i$, referring to the fact that this pair is calculated in terms of $E_i$. In terms of such a data structure, we give a naive algorithm below.

**Algorithm recursion($S$)**

begin
  for each $x \in S$ do {
    let $p_1, p_2, \ldots, p_m$ be the pair sequence associated with $x$;
    for $i = m$ to 1 do {
      let $\Delta$ be the set of descendants of $x$ w.r.t. $E_i$ (evaluated using $p_i$);
      for each $y \in \Delta$, remove the pair belonging to $E_i$ from the pair sequence associated with $y$;
      $\Delta_{\text{local}} := \Delta_{\text{local}} \cup \Delta_l$;
      $\Delta_{\text{global}} := \Delta_{\text{global}} \cup \Delta_l$;
      call recursion($\Delta_{\text{local}}$);
    }
  }
end

In the above algorithm, pay attention to the line marked with **, by which all the descendants of $x$ will be evaluated in $E_i$ using $p_i$. Since these descendants may appear also in other $E_j$, they should be used for the further computation. But the pair belonging to $E_i$ has to be eliminated from the pair sequences associated with these nodes to avoid the repeated access to the edges in $E_i$, which is done by the line marked with **.

The above algorithm suffers, however, from redundancy as discussed below.

The graph shown in Fig. 3(a) can be decomposed into two spanning trees as shown in Fig. 3(b). Applying recursion(7) to this graph, the descendant set evaluated in the first for loop is $\{4, 5\}$. In the second for loop, the descendants of node 4 and 5 will be computed, which are $s_1 = \{5, 6\}$ (the descendants of node 4) and $s_2 = \{6\}$ (the
descendants of node $s$), respectively. Obviously, $s$ is completely covered by $s$. Therefore, the work of evaluating $s$ can be saved. To this end, we associate each $E_i$ with a bit string of size $n$, denoted by $E$. If some node $j$ is a descendant evaluated w.r.t. $E_i$, the $j$th bit of $B$ will be set to 1, i.e., $B[j] = 1$. If the descendants of a node $k$ w.r.t. $E$ will be evaluated, we first check $B[k]$ to see whether it is equal to 1. If so, the corresponding computation will not be made. Another problem is that if $s$ is evaluated first, the redundant work can not be avoided even though the checking is performed. Thus, the order of the nodes whose descendants will be evaluated is important. For an $E_i$, the nodes with smaller preorder numbers will be treated earlier than those with a larger preorder number. It is because a node with a larger preorder number may be a descendant of a node with a smaller one, but not vice versa. In order to sort the nodes in this way, we have to change the control method of the above algorithm. Assume that each node $v$ is associated with a pair sequence of the form: $p_1, p_2, \ldots, p_m$, where $m$ is the largest in-degree of the graph. If $v$ does not appear in $E_i$, $p$ will be of the form: $(, )$ and will be ignored by sorting. The nodes, whose descendants w.r.t. $E_i$ are going to be evaluated, will be first sorted in terms of $p_i$. Then, the descendants of these nodes w.r.t. $E_i$ will be computed. In a second loop, the nodes will be sorted again in terms of $p_j$. This process repeats until all $p_j$'s are handled. Below is the corresponding al-gorithm with the checking mechanism used.

$$
\Delta_{\text{local}} := \emptyset; \\
\Delta_{\text{global}} := \emptyset; \\
\Delta := \{x\}; \quad (* \text{The descendants of } x \text{ will be searched. } *) \\
\text{let } p, p_2, \ldots, p_m \text{ be the pair sequence associated with each node of the graph;} \\
\text{for } i = 1 \text{ to } m \text{ do } B[i] = 0; \\
\text{function } \text{refined-recursion}(S) \begin{cases} \\
\text{begin} \\
\text{for } i = 1 \text{ to } m \text{ do } \\
\text{sort } S \text{ in terms of } p_i \text{'s; } \\
\text{let the sorted } S \text{ be } \{v_1, \ldots, v_j\}; \\
\text{for } j = 1 \text{ to } k \text{ do } \\
\text{if } B[v_j] = 0 \text{ then } \Delta \leftarrow \text{the set of descendants of } v_j \text{ w.r.t. } E_i \text{ (evaluated using } p_i); \\
\text{for each } v_j \in \Delta \text{ do } \\
\Delta_{\text{local}} := \Delta_{\text{local}} \cup \Delta \{v_j\} \\
\Delta_{\text{global}} := \Delta_{\text{global}} \cup \Delta_{\text{local}}; \\
call \text{refined-recursion}(\Delta_{\text{local}}); \\
\text{end} \\
\end{cases}
$$

Note that we take only $O(1)$ time to check a bit in the bit string. For each newly evaluated node set (each time stored in $\Delta_{\text{local}}$ in the above algorithm), sorting operations will be per-formed. But each node $v$ in $\Delta_{\text{local}}$ can take part in the sorting only $d$ times, where $d$ represents the in-degree of $v$, since for each node $v$ only $d$ pairs in the pair sequence associated with it is not of the form: $(, )$. Assume that each time only $\Delta$ from $\Delta_{\text{local}}$ participates in the sorting. Then, the total cost for sorting is

$$
\sum_{i} \sum_{j} |\Delta| \cdot \log |\Delta| \leq e \cdot \log n
$$

Since each edge is visited at most once, the traversal of the graph needs only $O(e)$ time. Therefore, the time complexity of the algorithm is bounded by $O(e \cdot \log n)$, little bit more than the time required by an algorithm using an adjacency list. But this algorithm is quite suitable for a relational environment. Furthermore, we can store the data in a special way to support the sorting operation so that no extra time is required. For example, we can define two simple relations to accommodate the graph and its pair sequences as follows:

$$
\text{node}(\text{Node_id}, \text{Node_rest}), \\
\text{spanning_forest}(\text{E_num}, \text{label_pair}, \text{Node_id}).
$$

The first relation stores all the nodes of the graph. The second relation stores all the spanning trees (forests), in which “E_num” is for the identifiers of the spanning trees (forests). If for each of them the label pairs are stored in the increasing order of their preorder numbers, the sorting operations in the algorithm refined-recursion() can be removed. Then, the time complexity of the algorithm can be reduced to $O(e)$. This can be done as follows. Whenever some $E_i$ is considered during the execution, we take the tuples with $E_{\text{num}} = i$ from the relation “spanning_forest”. Then, we scan these tuples and check, for each tuple, to see whether $B[$node_id$] = 1$. If it is the case, the corresponding label pair will be put in a list (a temporary data structure) sequentially. Obviously, the list constructed in this way is sorted into the increasing order of the preorder numbers w.r.t. $E_i$.

Recursion w.r.t. Cyclic Graphs

Based on the method discussed in the previous section, we can easily develop an algorithm to compute recursion for cyclic graphs. We can use Tarjan’s algorithm for identifying strong connected components (SCC) to find cycles of a cyclic graph [Ta72] (which needs only $O(n + e)$ time). Then, we think of each SCC as a single node (i.e., condense each SCC to a node). The resulting graph is a DAG. Applying the algorithm find_forest() to this DAG, we will get a set of forests. For each forest, we can associate each node with a pair as above. Obviously, all nodes in an SCC will be assigned the same pair (or the same pair sequence). For this reason, the method for evaluating the recursion at some node $x$ should be changed. For example, if a graph becomes a tree after con-densing each SCC to a node, the select-from-where state-ments like those given in Section 3 (against this graph) can be modified as follows. The first query is quite the same as that shown in Section 3:

$$
\begin{align*}
\text{SELECT} & \quad \text{label_pair} \\
\text{FROM} & \quad \text{Node} \\
\text{WHERE} & \quad \text{Node_id} = x \\
\text{But the second is changed slightly:} & \\
\text{SELECT} & \quad * \\
\text{FROM} & \quad \text{Node} \\
\text{WHERE} & \quad \text{label_pair.preorder $\leq$ preorder} \\
& \quad \text{and label_pair.postorder $\geq$ preorder} \\
\text{By the second query, the nodes in the same SCC as } x \text{ will be regarded as the descendants of } x.
\end{align*}
$$

For general cases, the method for checking ancestor-descendent relationship applies. No extra complexity is caused. Since Tarjan’s algorithm runs in $O(n + e)$ time, computing recursion for a cyclic graph needs only $O(e)$ time.

CONCLUSION

In this paper, a new labeling technique has been proposed. Using this technique, the recursion w.r.t. a tree hierarchy can be evaluated very efficiently. In addition, we have introduced a new algorithm for computing spanning trees (forests), which requires only linear time. Together with the labeling technique, this method enable us to develop an efficient algo-rithm to compute recursion for directed graphs in $O(e)$ time$^*$ where $e$ represents the number of the edges of the DAG.

Moreover, this method is especially suitable for relational databases and much better than the existing methods.

APPENDIX

In this Appendix, we trace the algorithm find-spanning-tree against the tree shown in Fig. 2(a).

See Fig. 4. At the beginning, every v is set to 0. After the first loop, the l-value of node 1 remains 0. But the l-values of 2, 6, and 7 are changed to 1. Moreover, node 1, and edge (1, 2), (1, 6) and (1, 7) are marked with “v” to indicate that have been visited. In addition, part of E, has been generated. The rest steps are listed in Fig. 5, 6, 7 and 8.
